ABSTRACT: A model to describe the low frequency dynamic and acoustic responses of a submarine hull subject to a harmonic propeller shaft excitation is presented. The submarine is modelled as a fluid-loaded, ring stiffened cylindrical shell with internal bulkheads and end caps. The stiffeners are introduced using a smeared approach. The bulkheads are modelled as circular plates and the end closures as truncated conical shells. The propeller introduces a harmonic axial force that is transmitted to the hull through the shaft and results in excitation of the accordion modes only if the force is symmetrically distributed to the hull. Structural and acoustic responses for the axisymmetric breathing modes are presented in terms of frequency response functions of the axial and radial displacements and directivity patterns for the radiated sound pressure.

1. INTRODUCTION
Vibration modes of a submerged hull are excited from the transmission of fluctuating forces through the shaft and thrust bearings due to the propeller rotation. These low frequency vibration modes of the hull can result in a high level of radiated noise. A hull can be idealised as a finite cylinder submerged in a fluid. The dynamic responses of cylindrical shells has received much research attention, ranging from the free vibrational characteristics of isotropic cylindrical shells subject to various boundary conditions [1, 2], to the effect of structural discontinuities such as stiffeners, a junction or changes in diameter on the wave propagation [3-5]. Thin cylindrical shells are often periodically stiffened in order to both increase stiffness and strength and reduce weight. Cylinders may be stiffened by circumferential rings, longitudinal stringers or both, in which the stiffeners are modelled as discrete elements [6-11] or their properties are averaged over the surface of the shell [12]. For submerged vessels, the effect of fluid loading on the structural and acoustic responses of cylindrical shells have been investigated [13-15].

In previous work by the authors [16], the submerged body was modelled as a ring-stiffened cylindrical shell with finite end closures and separated by bulkheads into a number of compartments. Excitation from the propeller/propulsion is idealised as an axial excitation acting at one end of the hull. This gives rise to excitation of the hull axisymmetric breathing modes associated with the zeroth circumferential mode number (n=0). This paper expands on this previous work to include the effect of end closures which are modelled as truncated conical shells. The forced response of the structure is calculated by solving the cylindrical shell displacements in the form of a wave solution and the conical shell in terms of a power series. An analytical expression for the radiated sound pressure from the structure is presented and accounts for the contributions from both the cylindrical hull and the end caps. Once the radial displacement of the structure is determined, the sound radiation in the far field is evaluated by modelling the submarine as a slender axisymmetric body for which the closed form solution of the Helmholtz equation is possible. The radiating surface is considered continuous. The scattering from the curvature discontinuity at the junction between the cylindrical and conical shells is neglected as well as the scattering at the external plates closing the conical shells. At low frequencies (<100 Hz), these effects are considered negligible.

2. DYNAMIC MODEL OF THE SUBMARINE HULL
Cylindrical shell
The submarine is modelled as a fluid loaded cylindrical shell with internal bulkheads and ring stiffeners. The hull is closed by means of end plates and truncated conical shells. The truncated cones are also closed at each end by circular plates. The model is illustrated in Figure 1. The main part of the submarine consists of a finite ring stiffened cylindrical shell closed at each end by two circular plates. The hull is partitioned into three parts by two equally spaced bulkheads. The ring stiffeners are modelled using smeared theory [12].
In Figure 2, \( u, v \) and \( w \) are the orthogonal components of displacement in the \( x, \theta \) and \( z \) directions, respectively. \( a \) is the mean radius of the cylindrical shell and \( h \) is the shell thickness.

![Figure 1. Schematic diagram of the submarine.](image)

**Figure 1.** Schematic diagram of the submarine.

**Figure 2.** Coordinate system and displacements for a thin walled cylindrical shell.

Variation to the differential equations of motion for thin cylindrical shells have been summarised by Leissa [1]. Flügge equations of motion were used and can be written in terms of a differential operator \( L_{ij} \) by [17]

\[
L_{11}u + L_{12}v + L_{13}w = 0
\]

\[
L_{22}u + L_{22}v + L_{23}w = 0
\]

\[
L_{32}v + L_{33}w - \frac{p}{\rho h c_t^2} = 0
\]

The elements of the matrix differential operator \( L_{ij} \) used in Eqs. (1) to (3) according to the Flügge theory can be found in the Appendix. \( c_t = \sqrt{\frac{E}{\rho(1-\nu^2)}} \) is the longitudinal wave speed. \( E, \rho \) and \( \nu \) are respectively the Young’s modulus, density and Poisson’s ratio of the cylinder. The external pressure loading \( p \) due to the fluid acting normally to the surface of the cylindrical shell can be approximated using an infinite model and expressed in terms of a fluid loading parameter \( F_L \) by [18]

\[
p = \frac{\rho h c_t^2}{a^2} F_L \times w
\]

\[
F_L = -\frac{\Omega^2 \rho a H_n'(k_w a)}{h \rho H_n'(k_w a)}
\]

where \( \Omega = \omega a / c_t \) is the non dimensional ring frequency, \( \rho_a \) is the density of the fluid. \( H_n \) is the Hankel function of order \( n \) and \( H_n' \) is its derivative with respect to the argument. \( k_w \) is the radial wavenumber [18]. The general solutions to the equations of motion can be written as

\[
w = \sum_{n=0}^{\infty} \sum_{j=1}^{\infty} W_{n,j} e^{jk_w x} \cos(n\theta)e^{-j\omega t}
\]

\[
u = \sum_{n=0}^{\infty} \sum_{j=1}^{\infty} G_{n,j} W_{n,j} e^{jk_w x} \sin(n\theta)e^{-j\omega t}
\]

where \( C_{n,j} = U_{n,j}/W_{n,j} \) and \( G_{n,j} = V_{n,j}/W_{n,j} \). \( k_{w,i} \) is the axial wavenumber and \( n \) is the circumferential mode number.

**End plates and bulkheads**

The end plates and bulkheads were modelled as thin circular plates in bending and in-plane motion. The axial \( w_p \), radial \( u_p \) and circumferential \( v_p \) plate displacements are shown in Figure 3. \( h_p \) is the plate thickness.

![Figure 3. Displacements for a thin circular plate.](image)

**Figure 3.** Displacements for a thin circular plate.

Displacements for the end plates and bulkheads can be written as [3]

\[
w_p = \sum_{n=0}^{\infty} \left( A_{n,1} J_n(k_{pB} a) + A_{n,2} I_n(k_{pB} a) \right) \cos(n\theta)e^{-j\omega t}
\]

\[
u_p = \sum_{n=0}^{\infty} \left( \frac{B_{n,1}}{a} \frac{\partial J_n(k_{pT} a)}{\partial a} + \frac{n B_{n,2}}{a} J_n(k_{pT} a) \right) \cos(n\theta)e^{-j\omega t}
\]

\[
u_p = \sum_{n=0}^{\infty} \left( \frac{B_{n,1}}{a} \frac{\partial J_n(k_{pT} a)}{\partial a} + \frac{n B_{n,2}}{a} J_n(k_{pT} a) \right) \cos(n\theta)e^{-j\omega t}
\]

where \( k_{pB} \) is the plate bending wavenumber and \( k_{pT} \), \( k_{pR} \) are the wavenumbers for in-plane waves in the plate [3]. \( J_n, I_n \) are respectively Bessel functions and modified Bessel functions of the first kind. The coefficients \( A_{n,j}, B_{n,j} \) are determined from the continuity equations at the cylinder/plate junctions.

**Conical shell**

Dynamic modelling of the conical shells can be found in [19]. The displacement of the conical shell was described using a power series solution following the procedure presented by Tong [20]. The displacements and coordinate system for the conical shell are shown in Figure 4, where \( u_t \) and \( v_t \) are respectively the displacements of the shell’s middle surface along the \( x_t \) and \( \theta_t \) directions. \( w_t \) is the displacement normal to the surface along the \( z_t \) direction.
External fluid loading on the conical shell was taken into account using a local cylindrical approximation which is described in what follows. The conical shell is divided in several narrow segments, as shown in Figure 5. The segments are narrow enough to be considered as locally cylindrical in order to account for the fluid loading; that is, the fluid loading on the conical strip is considered the same acting on an equivalent cylindrical shell with the same width and radius $R_c$. This approximation is only applicable to the calculation of the fluid loading acting on a shell segment. To solve for conical shell displacements, the equations of motion and corresponding general solutions for a conical shell were used. This method of accounting for the fluid loading acting on a conical shell using a local cylindrical approximation is shown to be reliable at low frequencies [19].

**Propeller shaft excitation**

The propeller force is transmitted to the edge of the cylindrical section of the hull. The transmitted force can be modelled as an axisymmetric distributed load given by $F=F_{\text{prop}}/2\pi a$ as shown in Figure 6. The distributed load excites only the $n=0$ breathing modes.

The dynamic response of the submarine for each value of the circumferential mode number $n$ is expressed in terms of $A_{nj}$ and $B_{nj}$ ($j=1,2$ for each circular plate) and $W_{nj}$ ($i=1:8$ for each section of the hull). The entire submarine is free-free. At the cylinder/plate junctions, continuity of displacements and equilibrium of forces/moments have to be satisfied. The whole structure consists of three cylindrical shell segments, six circular plates and two truncated conical shells. The boundary and continuity equations can be arranged in matrix form $\mathbf{B}\mathbf{x} = \mathbf{F}$, where $\mathbf{X}$ is the vector of unknown coefficients and $\mathbf{F}$ is the vector containing the external fluctuating forces from the propeller. Once the unknown coefficients have been determined the radial displacement of the hull can be obtained.

### 3. Far Field Sound Pressure

After the radial displacement of the structure has been determined, the far field sound pressure $P$ can be evaluated following the procedure presented by Skelton and James [21]. The submarine structure can be viewed as a slender body of revolution. The cylindrical coordinate systems are $(r, \theta, z)$ for the exterior body and $(r_{in}, \theta_{in}, z_{in})$ on the surface of the structure, as shown in Figure 7.

The angle $\beta$ is defined by $\tan \beta = \alpha_i(z_c)/\partial z_c$, where $a_i$ is the radius of the structure at location $z_c$ and $2L_\beta$ is the total length of the structure. The displacement normal to the surface, calculated solving the matrix $\mathbf{B}\mathbf{X} = \mathbf{F}$, can be written as

$$W_n(r_0, \theta_0, z_0) = \sum_{n=0}^{\infty} W_n(r_0, z_0) \cos(n \theta_0)$$

(12)

Considering a local approximation for the pressure near the surface of the body, the sound pressure in the far field can be calculated and expressed in polar coordinates by

$$P(R, \phi, \theta) = \frac{\alpha p_{f} c_f e^{jk_f R}}{2R} \sum_{n=0}^{\infty} j^n X_n(k_f \cos \phi) \cos(n \theta)$$

(13)

where

$$X_n(k_f \cos \phi) = \frac{I_n(k_f a_{in} \cos \beta)}{\alpha p_{f} c_f \cos \beta} e^{-j k_f \cos \phi z_0}$$

(14)

and

$$I_n(k_f a_{in} \cos \beta) = \frac{H_n(k_f a_{in} \cos \beta) \gamma \cos \beta H'_n(\gamma a_{in}) + j \alpha \sin \beta H_n(\gamma a_{in})}{\cos^2 \beta H'_n(k_f a_{in} \cos \beta) + j \sin^2 \beta H_n(k_f a_{in} \cos \beta)}$$

(15)

$k_i$ is the acoustic wavenumber and $c_i$ is the speed of sound in the medium. The integral in Eq. (14) can be calculated by considering separately the contribution of each section of the submarine corresponding to the conical and cylindrical shells. In this analysis, the surface is considered continuous.
Scattering from the curvature discontinuity at the junction between the cylindrical and conical shells and between the cones and the external plates are neglected.

4. RESULTS
Numerical results are presented for a ring-stiffened steel cylinder of radius $a=3.25$m, hull plate thickness $h=0.04$m, length $L=45$m and with two evenly spaced bulkheads of thickness $h_{b}=0.04$m. The end plates at each end of the cylinder are also of thickness $h_{cr}=0.04$m. The conical end enclosures are of dimensions $h_{c}=0.014$m, $R_{1}=0.50$m, $R_{2}=3.25$m, $a=\pi 10$rad. The material properties of steel are density $\rho=7800\text{kgm}^{-3}$, Young’s modulus $E=21\times10^{11}\text{Nm}^{-2}$ and Poisson’s ratio $\nu=0.3$. The stiffeners have a rectangular cross-sectional area of 0.08m x 0.15m and are evenly spaced by 0.5m. The cylinder was submerged in water ($\rho_{w}=1000\text{kgm}^{-3}$). The onboard equipment and ballast tanks are taken into account considering a distributed mass on the shell of $m_{w}=1500\text{kgm}^{-2}$. Internal structural damping was included in the analysis using a structural loss factor of 0.02. The submarine was excited with an axial force of unity amplitude $F_{x}=1\text{N}$ applied to one end of the finite cylindrical shell. Only the natural frequencies of the breathing modes defined by the $n=0$ circumferential mode were excited, resulting in axisymmetric motion of the hull. The structural results are presented in terms of the frequency response function of the axial and radial displacements at the ends of the cylindrical section. The acoustic results are presented in terms of the maximum sound pressure evaluated in the far field at $\theta_{e}=0$ and $R=1000$m.

Structural response
Figures 8 and 9 present the frequency response functions (FRFs) of the axial and radial displacements at each end of the cylindrical shell corresponding to $x=0$ and $L$. In Figure 8, the main peaks occurring at 22.7, 45.4 and 67.9 Hz are the first three resonant frequencies of the submarine for the axisymmetric case ($n=0$ breathing modes). The small peaks occurring at approximately 9 and 36 Hz are due to the bulkheads. The bulkhead resonances are more evident in Figure 9 which shows the radial displacement at each end of the cylindrical shell. As the axisymmetric modes are mainly axial in nature, the radial responses at the bulkhead natural frequencies are comparable with the responses at the resonances of the cylindrical shell.

The corresponding deformation shapes which are a combination of axial and radial displacements are shown in Figures 10 to 12 for the first three axisymmetric modes, respectively. Different scales are used for the horizontal and vertical axes in order to magnify the radial response. At the first and third resonant frequencies of 22.7 and 67.9 Hz respectively, the ends of the hull are vibrating out of phase with each other. At the second resonant frequency (Figure 11), the ends of the hull are vibrating in phase. The accordion motion of the hull results in large deformation in the axial direction and only a small radial expansion of the central cylindrical hull. The conical shells behave almost rigidly except for a small deformation at the junctions between the cylinder and end plates. The localised effect of the bulkheads on the radial displacement is shown. The effect of the ring stiffeners is not observed as the stiffeners were modelled using orthotropic shell properties. In all figures of the deformation shapes for the first three axisymmetric modes, the contribution of the orthotropic shell properties, the contribution from the radial response. At the first and third resonant frequencies of 22.7 and 67.9 Hz respectively, the ends of the hull are vibrating out of phase with each other. At the second resonant frequency (Figure 11), the ends of the hull are vibrating in phase. The accordion motion of the hull results in large deformation in the axial direction and only a small radial expansion of the central cylindrical hull. The conical shells behave almost rigidly except for a small deformation at the junctions between the cylinder and end plates. The localised effect of the bulkheads on the radial displacement is shown. The effect of the ring stiffeners is not observed as the stiffeners were modelled using orthotropic shell properties. In all figures of the deformation shapes for the first three axisymmetric modes, the contribution of the orthotropic shell properties, the contribution from the radial response.
Acoustic response
Figure 13 presents the maximum radiated sound pressure, which clearly shows the first three resonant frequencies of the submarine for the axisymmetric case ($n=0$ breathing modes). Small peaks due to the bulkheads are just visible. The radiation directivity patterns in terms of the angle $\phi$, are shown in Figures 14 to 16 for the first three axisymmetric modes of the submarine, respectively. The contribution from the cylindrical shell to the total radiated pressure is represented by the central lobes in the directivity patterns. The side lobes are due to the contribution from the end cones. As the frequency increases, the radiation directivity increases in complexity. For the first three resonances, there are one, two and three central lobes, respectively. In Figure 14, the directivity pattern shows that the contribution to the total sound pressure from the cones results in large lobes in the axial direction. A partial cancellation due to the pressure radiated by the cylindrical section occurs in the direction normal to the axis of the submarine. At the second natural frequency, the cylindrical section assumes a sinusoidal shape and its directivity pattern is bilobate. Similarly, at the third resonance, the radiated pressure from the central cylindrical shell is trilobate. As expected, the end cones determine the maximum sound pressure since the axisymmetric modes are mainly axial modes with little radial expansion.

5. CONCLUSIONS
An analytical model to study the low frequency structural and acoustic responses of a submerged vessel has been presented. Modelling of the submarine included several influencing factors corresponding to ring stiffeners, bulkheads and fluid-loading. The hull was closed by end plates and truncated conical shells. The truncated cones were solved using a power series solution whereas the hull was solved using a wave solution. The excitation from the propeller shaft results in an axisymmetric force distribution to the cylindrical hull which excites only the accordion modes of zeroth circumferential mode number. Results were presented in terms of frequency responses at each end of the cylindrical hull and of the maximum far field radiated sound pressure. Results were also presented for the deformation shapes and corresponding directivity patterns for the first three axisymmetric modes. Future work will involve extending the analytical model to include the effect of higher order circumferential modes, thus allowing the individual contributions from the higher order circumferential modes on the hull structural and acoustic responses to be observed. Furthermore, the development of an analytical model will allow the implementation of appropriate active control strategies to be investigated.
